    Pkg.activate(@__DIR__)
    Pkg.instantiate()
    using LinearAlgebra, Plots
    import ForwardDiff as FD
    using Test
    import Convex as cvx
    import ECOS
    using Random
    using MathOptInterface
Activating project at `~/OCRL/HW2_S25`
```

Note:

Some of the cells below will have multiple outputs (plots and animations), it can be easier to see everything if you do Cell
-> All Output -> Toggle Scrolling, so that it simply expands the output area to match the size of the outputs.

Julia Warnings:

- 1. For a function foo(x::Vector) with 1 input argument, it is not neccessary to do df_dx = FD.jacobian(_x -> foo(_x), x). Instead you can just do df_dx = FD.jacobian(foo, x). If you do the first one, it can dramatically slow down your compliation time.
- 2. Do not define functions inside of other functions like this:

```
function foo(x)
    # main function foo

function body(x)
    # function inside function (DON'T DO THIS)
    return 2*x
    end

return body(x)
end
```

This will also slow down your compilation time dramatically.

Q1: Finite-Horizon LQR (55 pts)

For this problem we are going to consider a "double integrator" for our dynamics model. This system has a state $x \in \mathbb{R}^4$, and control $u \in \mathbb{R}^2$, where the state describes the 2D position p and velocity v of an object, and the control is the acceleration a of this object. The state and control are the following:

$$x = [p_1, p_2, v_1, v_2]$$
 (1)
 $u = [a_1, a_2]$ (2)

And the continuous time dynamics for this system are the following:

$$\dot{x} = \begin{bmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} x + \begin{bmatrix} 0 & 0 \\ 0 & 0 \\ 1 & 0 \\ 0 & 1 \end{bmatrix}$$

$$(3)u$$

Part A: Discretize the model (5 pts)

Use the matrix exponential (exp in Julia) to discretize the continuous time model assuming we have a zero-order hold on the control. See this part of the first recitation if you're unsure of what to do.

```
In [2]: # double integrator dynamics
function double_integrator_AB(dt)::Tuple{Matrix,Matrix}
```

```
Ac = [0 \ 0 \ 1 \ 0;
          0 0 0 1:
          0 0 0 0;
          0 0 0 0.]
    Bc = [0 \ 0;
          0 0;
          1 0;
          0 1]
    nx, nu = size(Bc)
    # TODO: discretize this linear system using the Matrix Exponential
    ode_mat = exp([Ac*dt Bc*dt; zeros(nu,nx) zeros(nu,nu)])
    A = ode_mat[1:nx, 1:nx] # TODO
    B = ode_mat[1:nx, nx+1:end] # TODO
    @assert size(A) == (nx,nx)
    @assert size(B) == (nx,nu)
    return A, B
end
```

double_integrator_AB (generic function with 1 method)

Test Summary: | Pass Total Time discrete time dynamics | 1 1 5.2s
Test.DefaultTestSet("discrete time dynamics", Any[], 1, false, false, true, 1.739658545317046e9, 1.739658550542337e9, false, "/home/burger/OCRL/HW2_S25/jl_notebook_cell_df34fa98e69747e1a8f8a730347b8e2f_W6sZml sZQ==.jl")

Part B: Finite Horizon LQR via Convex Optimization (15 pts)

We are now going to solve the finite horizon LQR problem with convex optimization. As we went over in class, this problem requires $Q \in S_+$ (Q is symmetric positive semi-definite) and $R \in S_{++}$ (R is symmetric positive definite). With this, the optimization problem can be stated as the following:

$$\min_{x_{1:N}, u_{1:N-1}} \quad \sum_{i=1}^{N-1} \left[\frac{1}{2} x_i^T Q x_i + \frac{1}{2} u_i^T R u_i \right] + \frac{1}{2} x_N^T Q_f x_N \tag{4}$$

$$st x_1 = x_{IC} (5)$$

$$x_{i+1} = Ax_i + Bu_i \quad \text{for } i = 1, 2, \dots, N-1$$
 (6)

This problem is a convex optimization problem since the cost function is a convex quadratic and the constraints are all linear equality constraints. We will setup and solve this exact problem using the Convex.jl modeling package. (See 2/16 Recitation video for help with this package. Notebook is here.) Your job in the block below is to fill out a function Xcvx,Ucvx = convex_trajopt(A,B,Q,R,Qf,N,x_ic), where you will form and solve the above optimization problem.

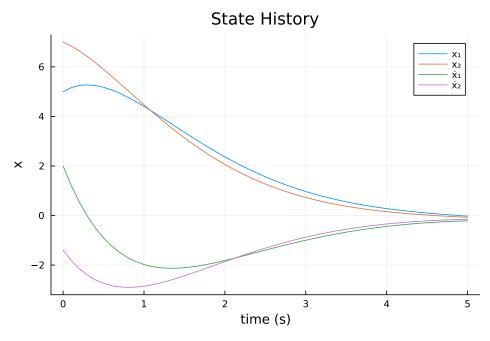

```
0.000
X,U = convex_trajopt(A,B,Q,R,Qf,N,x_ic; verbose = false)
This function takes in a dynamics model x_{k+1} = A*x_k + B*u_k
and LQR cost Q,R,Qf, with a horizon size N, and initial condition
x_ic, and returns the optimal X and U's from the above optimization
problem. You should use the `vec_from_mat` function to convert the
solution matrices from cvx into vectors of vectors (vec_from_mat(X.value))
                                       # A matrix
function convex_trajopt(A::Matrix,
                        B::Matrix,
                                       # B matrix
                        Q::Matrix,
                                       # cost weight
                        R::Matrix,
                                       # cost weight
                        Qf::Matrix,
                                       # term cost weight
                                       # horizon size
                        N::Int64,
                        x ic::Vector; # initial condition
                        verbose = false
                        )::Tuple{Vector{Vector{Float64}}}, Vector{Vector{Float64}}}
    # check sizes of everything
    nx,nu = size(B)
    @assert size(A) == (nx, nx)
    @assert size(Q) == (nx, nx)
    @assert size(R) == (nu, nu)
    @assert size(Qf) == (nx, nx)
    @assert length(x_ic) == nx
    # TOD0:
    # create cvx variables where each column is a time step
    X = cvx.Variable(nx, N)
    U = cvx.Variable(nu, N - 1)
    # create cost
    # hint: you can't do x'*Q*x in Convex.jl, you must do cvx.quadform(x,Q)
    # hint: add all of your cost terms to `cost`
    # hint: x_k = X[:,k], u_k = U[:,k]
    cost = 0
    for k = 1:(N-1)
       x_k = X[:,k]
       u_k = U[:,k]
        quadform_x = 0.5 * cvx_quadform(x_k,Q)
        quadform u = 0.5 * cvx.quadform(u k,R)
        # add stagewise cost
        cost += quadform x + quadform u
    end
    # add terminal cost
    cost += 0.5 * cvx.quadform(X[:,N],Qf)
    # initialize cvx problem
    prob = cvx.minimize(cost)
    # TODO: initial condition constraint
    # hint: you can add constraints to our problem like this:
    # prob.constraints = vcat(prob.constraints, (Gz == h))
    prob.constraints = vcat(prob.constraints, (X[:,1] == x_ic))
    for k = 1:(N-1)
       # dynamics constraints
        prob.constraints = vcat(prob.constraints, (X[:,k+1] == A*X[:,k] + B*U[:,k]))
    end
    # solve problem (silent solver tells us the output)
    cvx.solve!(prob, ECOS.Optimizer; silent = !verbose)
    if prob.status != MathOptInterface.OPTIMAL
        error("Convex.jl problem failed to solve for some reason")
    # convert the solution matrices into vectors of vectors
    X = vec from mat(X.value)
    U = vec_from_mat(U.value)
```

```
return X, U end
```

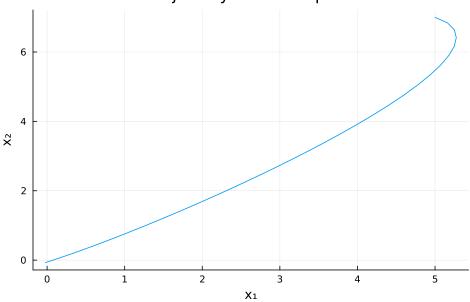

convex_trajopt

Now let's solve this problem for a given initial condition, and simulate it to see how it does:

```
In [5]: @testset "LQR via Convex.jl" begin
            # problem setup stuff
            dt = 0.1
            tf = 5.0
            t vec = 0:dt:tf
            N = length(t_vec)
            A,B = double_integrator_AB(dt)
            nx,nu = size(B)
            Q = diagm(ones(nx))
            R = diagm(ones(nu))
            Qf = 5*Q
            # initial condition
            x_ic = [5,7,2,-1.4]
            # setup and solve our convex optimization problem (verbose = true for submission)
            Xcvx,Ucvx = convex_trajopt(A,B,Q,R,Qf,N,x_ic; verbose = false)
            # TODO: simulate with the dynamics with control Ucvx, storing the
            # state in Xsim
            # initial condition
            Xsim = [zeros(nx) for i = 1:N]
            Xsim[1] = 1*x_ic

Trajectory in State Space

Pass Test Summary: Total Time LQR via Convex.jl | 6 15.3s

Test.DefaultTestSet("LQR via Convex.jl", Any[], 6, false, false, true, 1.73965855117871e9, 1.73965856652 8077e9, false, "/home/burger/OCRL/HW2_S25/jl_notebook_cell_df34fa98e69747e1a8f8a730347b8e2f_X14sZmlsZQ= =.jl")

Bellman's Principle of Optimality

Now we will test Bellman's Principle of optimality. This can be phrased in many different ways, but the main gist is that any section of an optimal trajectory must be optimal. Our original optimization problem was the above problem:

$$\min_{x_{1:N}, u_{1:N-1}} \sum_{i=1}^{N-1} \left[\frac{1}{2} x_i^T Q x_i + \frac{1}{2} u_i^T R u_i \right] + \frac{1}{2} x_N^T Q_f x_N$$
st $x_1 = x_{\text{IC}}$ (8)

st
$$x_1 = x_{\text{IC}}$$
 (8)

$$x_1 = x_{\text{IC}}$$
 (8)
 $x_{i+1} = Ax_i + Bu_i$ for $i = 1, 2, ..., N-1$ (9)

which has a solution $x_{1:N}^*, u_{1:N-1}^*$. Now let's look at optimizing over a subsection of this trajectory. That means that instead of solving for $x_{1:N}, u_{1:N-1}$, we are now solving for $x_{L:N}, u_{L:N-1}$ for some new timestep 1 < L < N. What we are going to do is take the initial condition from x_L^st from our original optimization problem, and setup a new optimization problem that optimizes over $x_{L:N}, u_{L:N-1}$:

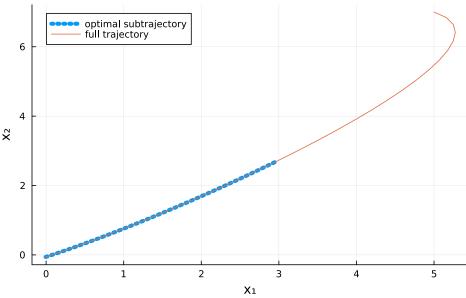

$$\min_{x_{L:N}, u_{L:N-1}} \sum_{i=L}^{N-1} \left[\frac{1}{2} x_i^T Q x_i + \frac{1}{2} u_i^T R u_i \right] + \frac{1}{2} x_N^T Q_f x_N$$
 (10)

$$st x_L = x_L^* (11)$$

```
x_{i+1} = Ax_i + Bu_i \quad \text{for } i = L, L+1, \dots, N-1 (12)
```

```
In [6]: @testset "Bellman's Principle of Optimality" begin
           # problem setup
           dt = 0.1
           tf = 5.0
           t_vec = 0:dt:tf
           N = length(t_vec)
           A,B = double_integrator_AB(dt)
           nx,nu = size(B)
           x0 = [5,7,2,-1.4] # initial condition
           Q = diagm(ones(nx))
           R = diagm(ones(nu))
           Qf = 5*Q
            # solve for X {1:N}, U {1:N-1} with convex optimization
           Xcvx1,Ucvx1 = convex_trajopt(A,B,Q,R,Qf,N,x0; verbose = false)
           # now let's solve a subsection of this trajectory
           L = 18
           N_2 = N - L + 1
           # here is our updated initial condition from the first problem
           x0_2 = Xcvx1[L]
           Xcvx2,Ucvx2 = convex\_trajopt(A,B,Q,R,Qf,N_2,x0_2; verbose = false)
           # test if these trajectories match for the times they share
           U_error = Ucvx1[L:end] .- Ucvx2
           X_error = Xcvx1[L:end] .- Xcvx2

        end
```

Trajectory in State Space

Part C: Finite-Horizon LQR via Riccati (10 pts)

Now we are going to solve the original finite-horizon LQR problem:

$$\min_{x_{1:N}, u_{1:N-1}} \quad \sum_{i=1}^{N-1} \left[\frac{1}{2} x_i^T Q x_i + \frac{1}{2} u_i^T R u_i \right] + \frac{1}{2} x_N^T Q_f x_N$$
 (13)

$$x_1 = x_{\rm IC} \tag{14}$$

$$x_{i+1} = Ax_i + Bu_i \quad \text{for } i = 1, 2, \dots, N-1$$
 (15)

with a Riccati recursion instead of convex optimization. We describe our optimal cost-to-go function (aka the Value function) as the following:

$$V_k(x) = \frac{1}{2}x^T P_k x.$$

```
In [7]: """
        use the Riccati recursion to calculate the cost to go quadratic matrix P and
        optimal control gain K at every time step. Return these as a vector of matrices,
        where P_k = P[k], and K_k = K[k]
        function fhlqr(A::Matrix, # A matrix
                       B::Matrix, # B matrix
                       Q::Matrix, # cost weight
                       R::Matrix, # cost weight
                       Qf::Matrix,# term cost weight
                       N::Int64 # horizon size
                       )::Tuple{Vector{Matrix{Float64}}}, Vector{Matrix{Float64}}} # return two matrices
            # check sizes of everything
            nx,nu = size(B)
            @assert size(A) == (nx, nx)
            @assert size(Q) == (nx, nx)
            @assert size(R) == (nu, nu)
            @assert size(Qf) == (nx, nx)

Trajectory in State Space

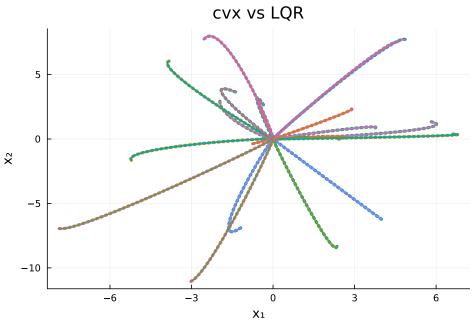

```
Test Summary: | Pass Total Time Convex trajopt vs LQR | 3 3 1.0s Test.DefaultTestSet("Convex trajopt vs LQR", Any[], 3, false, false, true, 1.739658566927528e9, 1.739658567916644e9, false, "/home/burger/OCRL/HW2_S25/jl_notebook_cell_df34fa98e69747e1a8f8a730347b8e2f_X22sZml sZQ==.jl")
```

To emphasize that these two methods for solving the optimization problem result in the same solutions, we are now going to sample initial conditions and run both solutions. You will have to fill in your LQR policy again.

```
In [9]: import Random

end
```

Part D: Why LQR is so great (10 pts)

Now we are going to emphasize two reasons why the feedback policy from LQR is so useful:

- 1. It is robust to noise and model uncertainty (the Convex approach would require re-solving of the problem every time the new state differs from the expected state (this is MPC, more on this in Q3)
- 2. We can drive to any achievable goal state with $u=-K(x-x_{qoal})$

First we are going to look at a simulation with the following white noise:

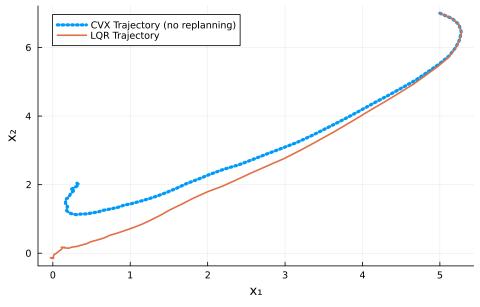

$$x_{k+1} = Ax_k + Bu_k + \text{noise}$$

Where noise $\sim \mathcal{N}(0,\Sigma)$.

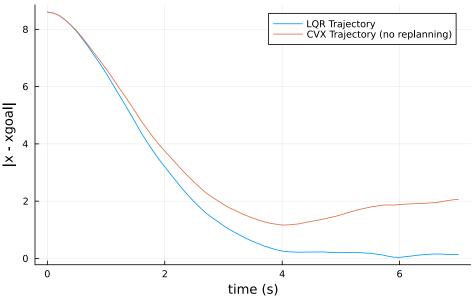

```
In [10]: @testset "Why LQR is great reason 1" begin
             # problem stuff

Trajectory in State Space

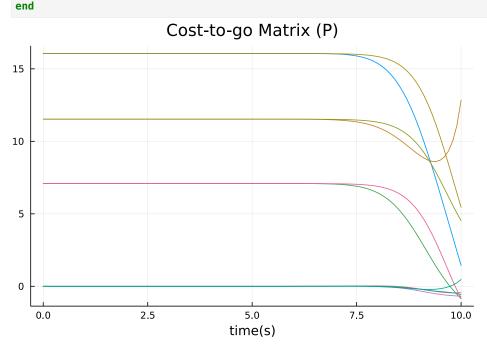

Part E: Infinite-horizon LQR (10 pts)

Up until this point, we have looked at finite-horizon LQR which only considers a finite number of timesteps in our trajectory. When this problem is solved with a Riccati recursion, there is a new feedback gain matrix K_k for each timestep. As the length of the trajectory increases, the first feedback gain matrix K_1 will begin to converge on what we call the "infinite-horizon LQR gain". This is the value that K_1 converges to as $N \to \infty$.

Below, we will plot the values of P and K throughout the horizon and observe this convergence.

```
In [16]: # half vectorization of a matrix
          function vech(A)
              return A[tril(trues(size(A)))]
          @testset "P and K time analysis" begin
              # problem stuff
              dt = 0.1
              tf = 10.0
              t_{vec} = 0:dt:tf
              N = length(t_vec)
              A,B = double_integrator_AB(dt)
              nx,nu = size(B)
              # cost terms
              Q = diagm(ones(nx))
              R = .5*diagm(ones(nu))
              Qf = randn(nx,nx); Qf = Qf'*Qf + I;
              P, K = fhlqr(A,B,Q,R,Qf,N)
              Pm = hcat(vech.(P)...)
              Km = hcat(vec.(K)...)
              # make sure these things converged
              @test le-13 < norm(P[1] - P[2]) < le-3 @test le-13 < norm(K[1] - K[2]) < le-3
              display(plot(t_vec, Pm', label = "",title = "Cost-to-go Matrix (P)", xlabel = "time(s)"))
              display(plot(t_vec[1:end-1], Km', label = "", title = "Gain Matrix (K)", xlabel = "time(s)"))
```

Gain Matrix (K) 2.0 1.5 1.0 0.0 2.5 5.0 7.5 10.0 time(s)

Complete this infinite horizon LQR function where you do a Riccati recursion until the cost to go matrix P converges:

$$||P_k - P_{k+1}|| \le \text{tol}$$

And return the steady state P and K.

```
tol = 1e-5 # convergence tolerance
               )::Tuple{Matrix, Matrix} # return two matrices
    \# get size of x and u from B

plot_basin_of_attraction (generic function with 1 method)

Note:

Some of the cells below will have multiple outputs (plots and animations), it can be easier to see everything if you do Cell
-> All Output -> Toggle Scrolling, so that it simply expands the output area to match the size of the outputs.

Q2: LQR for nonlinear systems (40 pts)

Linearization warmup

Before we apply LQR to nonlinear systems, we are going to treat our linear system as if it's nonlinear. Specifically, we are going to "approximate" our linear system with a first-order Taylor series, and define a new set of $(\Delta x, \Delta u)$ coordinates. Since our dynamics are linear, this approximation is exact, allowing us to check that we set up the problem correctly.

First, assume our discrete time dynamics are the following:

$$x_{k+1} = f(x_k, u_k)$$

And we are going to linearize about a reference trajectory $\bar{x}_{1:N}, \bar{u}_{1:N-1}$. From here, we can define our delta's accordingly:

$$x_k = \bar{x}_k + \Delta x_k \tag{1}$$

$$u_k = \bar{u}_k + \Delta u_k \tag{2}$$

Next, we are going to approximate our discrete time dynamics function with the following first order Taylor series:

$$egin{split} x_{k+1} &pprox f(ar{x}_k, ar{u}_k) + iggl[rac{\partial f}{\partial x}iggr|_{ar{x}_k, ar{u}_k}iggr](x_k - ar{x}_k) + iggl[rac{\partial f}{\partial u}iggr|_{ar{x}_k, ar{u}_k}iggr](u_k - ar{u}_k) \end{split}$$

Which we can substitute in our delta notation to get the following:

$$ar{x}_{k+1} + \Delta x_{k+1} pprox f(ar{x}_k, ar{u}_k) + iggl[rac{\partial f}{\partial x} iggr|_{ar{x}_k, ar{u}_k} iggr] \Delta x_k + iggl[rac{\partial f}{\partial u} iggr|_{ar{x}_k, ar{u}_k} iggr] \Delta u_k$$

If the trajectory \bar{x}, \bar{u} is dynamically feasible (meaning $\bar{x}_{k+1} = f(\bar{x}_k, \bar{u}_k)$), then we can cancel these equivalent terms on each side of the above equation, resulting in the following:

$$\Delta x_{k+1}pprox igg[rac{\partial f}{\partial x}igg|_{ar{x}_k,ar{u}_k}igg]\Delta x_k + igg[rac{\partial f}{\partial u}igg|_{ar{x}_k,ar{u}_k}igg]\Delta u_k$$

Cartpole

We are now going to look at two different applications of LQR to the nonlinear cartpole system. Given the following description of the cartpole:

```
No description has been provided for this image
```

(if this image doesn't show up, check out `cartpole.png`)

with a cart position p and pole angle θ . We are first going to linearize the nonlinear discrete dynamics of this system about the point where p=0, and $\theta=0$ (no velocities), and use an infinite horizon LQR controller about this linearized state to stabilize the cartpole about this goal state. The dynamics of the cartpole are parametrized by the mass of the cart, the mass of the pole, and the length of the pole. To simulate a "sim to real gap", we are going to design our controllers around an estimated set of problem parameters params_est , and simulate our system with a different set of problem parameters params_real .

```
In [2]: """
         continuous time dynamics for a cartpole, the state is
         x = [p, \theta, \dot{p}, \theta]
         where p is the horizontal position, and \theta is the angle
         where \theta = 0 has the pole hanging down, and \theta = 180 is up.
         The cartpole is parametrized by a cart mass `mc`, pole
         mass `mp`, and pole length `l`. These parameters are loaded into a `params::NamedTuple`. We are going to design the
         controller for a estimated `params_est`, and simulate with
          `params_real`.
         function dynamics(params::NamedTuple, x::Vector, u)
             # cartpole ODE, parametrized by params.
             # cartpole physical parameters
             mc, mp, l = params.mc, params.mp, params.l
             g = 9.81
             q = x[1:2]
             qd = x[3:4]
             s = sin(q[2])
             c = cos(q[2])
             H = [mc+mp mp*l*c; mp*l*c mp*l^2]
             C = [0 - mp*qd[2]*l*s; 0 0]
             G = [0, mp*g*l*s]
             B = [1, 0]
             qdd = -H \setminus (C*qd + G - B*u[1])
             return [qd;qdd]
         end
         # true nonlinear dynamics of the system
         # if I want to simulate, this is what I do
         function rk4(params::NamedTuple, x::Vector,u,dt::Float64)
             # vanilla RK4
             k1 = dt*dynamics(params, x, u)
             k2 = dt*dynamics(params, x + k1/2, u)
             k3 = dt*dynamics(params, x + k2/2, u)
             k4 = dt*dynamics(params, x + k3, u)
             return x + (1/6)*(k1 + 2*k2 + 2*k3 + k4)
```

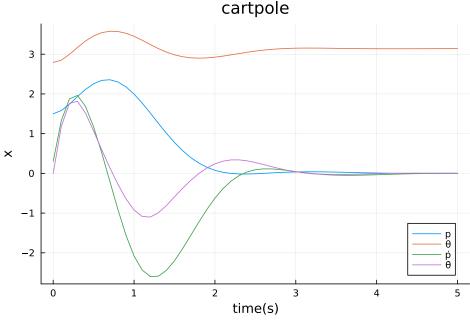

rk4 (generic function with 1 method)

Part A: Infinite Horizon LQR about an equilibrium (10 pts)

Here we are going to solve for the infinite horizon LQR gain, and use it to stabilize the cartpole about the unstable equilibrium.

```
In [3]: @testset "LQR about eq" begin
            # states and control sizes

Part B: Infinite horizon LQR basin of attraction (5 pts)

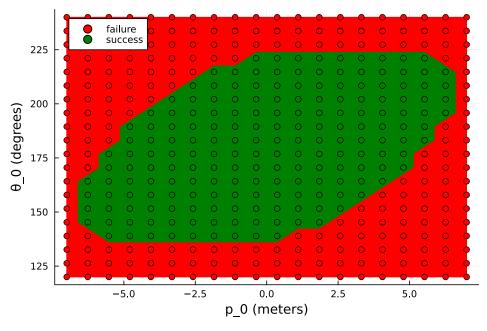

2/20/25, 12:57 4 of 11

In part A we built a controller for the cartpole that was based on a linearized version of the system dynamics. This linearization took place at the (xgoal, ugoal), so we should only really expect this model to be accurate if we are close to this linearization point (think small angle approximation). As we get further from the goal state, our linearized model is less and less accurate, making the performance of our controller suffer. At a certain point, the controller is unable to stabilize the cartpole due to this model mismatch.

To demonstrate this, you are now being asked to take the same controller you used above, and try it for a range of initial conditions. For each of these simulations, you will determine if the controller was able to stabilize the cartpole. From here, you will plot the successes and failures on a plot and visualize a "basin of attraction", that is, a region of the state space where we expect our controller to stabilize the system.

```
In [4]: function create_initial_conditions()
            # create a span of initial configurations
            M = 20
            ps = LinRange(-7, 7, M)

Part C: Infinite horizon LQR cost tuning (5 pts)

We are now going to tune the LQR cost to satisfy our following performance requirement:

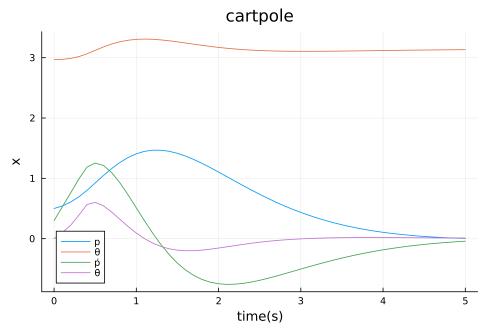

```
\|x(5.0)-x_{
m goal}\|_2={\sf norm}({\sf X[N]} - xgoal) < 0.1
```

which says that the L2 norm of the state at 5 seconds (last timestep in our simulation) should be less than 0.1. We are also going to have to deal with the following actuator limits: $-3 \le u \le 3$. You won't be able to directly reason about this actuator limit in our LQR controller, but we can tune our cost function to avoid saturating the actuators (reaching the actuator limits) for too long. Here are our suggestions for tuning successfully:

- 1. First, adjust the values in Q and R to find a controller that stabilizes the cartpole. The key here is tuning our cost to keep the control away from the actuator limits for too long.
- 2. Now that you can stabilize the system, the next step is to tune the values in Q and R accomplish our performance goal of norm(X[N] xgoal) < 0.1. Think about the individual values in Q, and which states we really want to penalize. The positions (p, θ) should be penalized differently than the velocities $(\dot{p}, \dot{\theta})$.

```

Notes:

- 1. Some of the cells below will have multiple outputs (plots and animations), it can be easier to see everything if you do Cell -> All Output -> Toggle Scrolling, so that it simply expands the output area to match the size of the outputs.
- 2. Things in space move very slowly (by design), because of this, you may want to speed up the animations when you're viewing them. You can do this in MeshCat by doing Open Controls -> Animations -> Time Scale, to modify the time scale. You can also play/pause/scrub from this menu as well.
- 3. You can move around your view in MeshCat by clicking + dragging, and you can pan with right click + dragging, and zoom with the scroll wheel on your mouse (or trackpad specific alternatives).

vec_from_mat (generic function with 1 method)

Is LQR the answer for everything?

Unfortunately, no. LQR is great for problems with true quadratic costs and linear dynamics, but this is a very small subset of convex trajectory optimization problems. While a quadratic cost is common in control, there are other available convex cost functions that may better motivate the desired behavior of the system. These costs can be things like an L1 norm on the control inputs ($\|u\|_1$), or an L2 goal error ($\|x-x_{goal}\|_2$). Also, control problems often have constraints like path constraints, control bounds, or terminal constraints, that can't be handled with LQR. With the addition of these constraints, the trajectory optimization problem is stil convex and easy to solve, but we can no longer just get an optimal gain K and apply a feedback policy in these situations.

The solution to this is Model Predictive Control (MPC). In MPC, we are setting up and solving a convex trajectory optimization at every time step, optimizing over some horizon or window into the future, and executing the first control in the solution. To see how this works, we are going to try this for a classic space control problem: the rendezvous.

Q3: Optimal Rendezvous and Docking (55 pts)

In this example, we are going to use convex optimization to control the SpaceX Dragon 1 spacecraft as it docks with the International Space Station (ISS). The dynamics of the Dragon vehicle can be modeled with Clohessy-Wiltshire equations, which is a linear dynamics model in continuous time. The state and control of this system are the following:

$$x = [r_x, r_y, r_z, v_x, v_y, v_z]^T, (1)$$

$$u = [t_x, t_y, t_z]^T, \tag{2}$$

where r is a relative position of the Dragon spacecraft with respect to the ISS, v is the relative velocity, and t is the thrust on the spacecraft. The continuous time dynamics of the vehicle are the following:

$$\dot{x} = \begin{bmatrix} 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 3n^2 & 0 & 0 & 0 & 2n & 0 \\ 0 & 0 & 0 & -2n & 0 & 0 \\ 0 & 0 & -n^2 & 0 & 0 & 0 \end{bmatrix} + \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} u, \tag{3}$$

where $n=\sqrt{\mu/a^3}$, with μ being the standard gravitational parameter, and a being the semi-major axis of the orbit of the ISS.

We are going to use three different techniques for solving this control problem, the first is LQR, the second is convex trajectory optimization, and the third is convex MPC where we will be able to account for unmodeled dynamics in our system (the "sim to real" gap).

Part A: Discretize the dynamics (5 pts)

Use the matrix exponential to convert the linear ODE into a linear discrete time model (hint: the matrix exponential is just exp() in Julia when called on a matrix.

create_dynamics (generic function with 1 method)

Part B: LQR (10 pts)

Now we will take a given reference trajectory X_ref and track it with finite-horizon LQR. Remember that finite-horizon LQR is solving this problem:

$$\min_{x_{1:N}, u_{1:N-1}} \quad \sum_{i=1}^{N-1} \left[\frac{1}{2} (x_i - x_{ref,i})^T Q(x_i - x_{ref,i}) + \frac{1}{2} u_i^T R u_i \right] + \frac{1}{2} (x_N - x_{ref,N})^T Q_f(x_N - x_{ref,N}) \tag{4}$$

$$t \quad x_1 = x_{\rm IC} \tag{5}$$

$$x_{i+1} = Ax_i + Bu_i \quad \text{for } i = 1, 2, \dots, N-1$$
 (6)

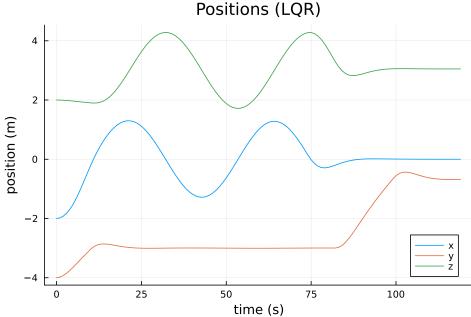

where our policy is $u_i = -K_i(x_i - x_{ref,i})$. Use your code from the previous problem with your fhlqr function to generate your gain matrices.

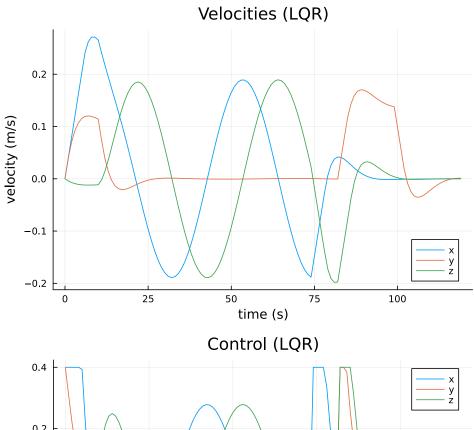

One twist we will throw into this is control constraints u_min and u_max . You should use the function clamp.(u, u_min, u_max) to clamp the values of your u to be within this range.

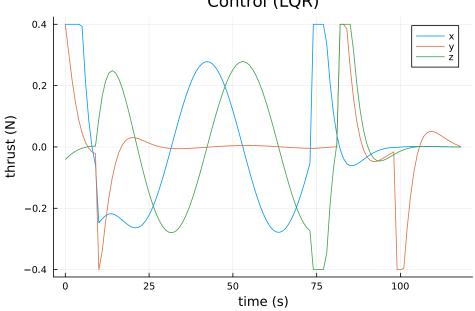

If implemented correctly, you should see the Dragon spacecraft dock with the ISS successfuly, but only after it crashes through the ISS a little bit.

```
In [5]: @testset "LQR rendezvous" begin

Part C: Convex Trajectory Optimization (15 pts)

Now we are going to assume that we have a perfect model (assume there is no sim to real gap), and that we have a perfect state estimate. With this, we are going to solve our control problem as a convex trajectory optimization problem.

$$\min_{x_{1:N}, u_{1:N-1}} \sum_{i=1}^{N-1} \left[\frac{1}{2} (x_i - x_{ref,i})^T Q(x_i - x_{ref,i}) + \frac{1}{2} u_i^T R u_i \right]$$
(7)

st
$$x_1 = x_{IC}$$
 (8)

$$x_{i+1} = Ax_i + Bu_i \quad \text{for } i = 1, 2, \dots, N-1$$
 (9)

$$u_{min} \le u_i \le u_{max} \quad \text{for } i = 1, 2, \dots, N - 1$$
 (10)

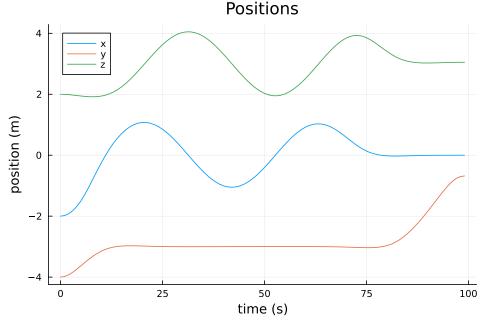

$$x_i[2] \le x_{goal}[2] \quad \text{for } i = 1, 2, \dots, N$$
 (11)

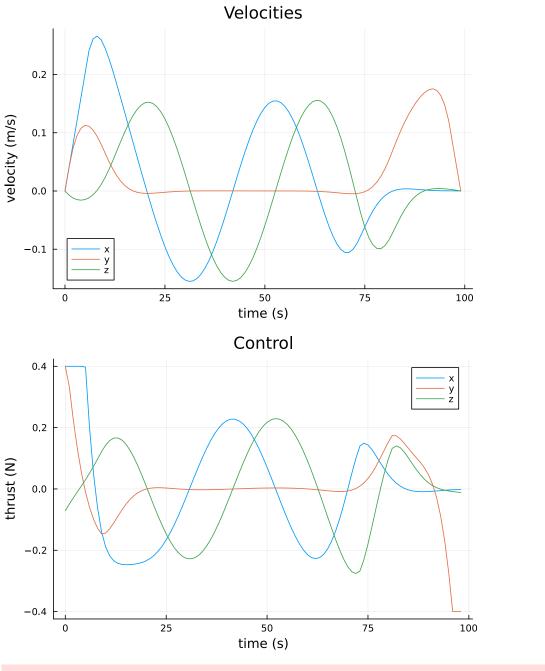

$$x_N = x_{goal} \tag{12}$$

Where we have an LQR cost, an initial condition constraint $(x_1=x_{\rm IC})$, linear dynamics constraints $(x_{i+1}=Ax_i+Bu_i)$, bound constraints on the control ($\leq u_i \leq u_{max}$), an ISS collision constraint ($x_i[2] \leq x_{goal}[2]$), and a terminal constraint ($x_i = x_{goal}$). This problem is convex and we will setup and solve this with Convex.jl.

Open Controls

Part D: Convex MPC (20 pts)

In part C, we solved for the optimal rendezvous trajectory using convex optimization, and verified it by simulating it in an open loop fashion (no feedback). This was made possible because we assumed that our linear dynamics were exact, and that we had a perfect estimate of our state. In reality, there are many issues that would prevent this open loop policy from being successful; Here are a few:

- imperfect state estimation
- unmodeled dynamics
- misalignments
- actuator uncertainties

Together, these factors result in a "sim to real" gap between our simulated model, and the real model. Because there will always be a sim to real gap, we can't just execute open loop policies and expect them to be successful. What we can do, however, is use Model Predictive Control (MPC) that combines some of the ideas of feedback control with convex trajectory optimization.

A convex MPC controller will set up and solve a convex optimization problem at each time step that incorporates the current state estimate as an initial condition. For a trajectory tracking problem like this rendezvous, we want to track x_{ref} , but instead of optimizing over the whole trajectory, we will only consider a sliding window of size N_{mpc} (also called a horizon). If $N_{mpc}=20$, this means our convex MPC controller is reasoning about the next 20 steps in the trajectory. This optimization problem at every timestep will start by taking the relevant reference trajectory at the current window from the current step i, to the end of the window $i+N_{mpc}-1$. This slice of the reference trajectory that applies to the current MPC window will be called $\tilde{x}_{ref}=x_{ref}[i,(i+N_{mpc}-1)]$.

$$\min_{x_{1:N}, u_{1:N-1}} \sum_{i=1}^{N-1} \left[\frac{1}{2} (x_i - \tilde{x}_{ref,i})^T Q(x_i - \tilde{x}_{ref,i}) + \frac{1}{2} u_i^T R u_i \right] + \frac{1}{2} (x_N - \tilde{x}_{ref,N})^T Q(x_N - \tilde{x}_{ref,N})$$
(13)

st
$$x_1 = x_{\rm IC}$$
 (14)

$$x_{i+1} = Ax_i + Bu_i \quad \text{for } i = 1, 2, \dots, N-1$$
 (15)

$$u_{min} \le u_i \le u_{max} \quad \text{for } i = 1, 2, \dots, N - 1$$
 (16)

$$x_i[2] \le x_{goal}[2] \quad \text{for } i = 1, 2, \dots, N$$
 (17)

where N in this case is N_{mpc} . This allows for the MPC controller to "think" about the future states in a way that the LQR controller cannot. By updating the reference trajectory window (\tilde{x}_{ref}) at each step and updating the initial condition (x_{IC}), the MPC controller is able to "react" and compensate for the sim to real gap.

You will now implement a function convex_mpc where you setup and solve this optimization problem at every timestep, and simply return u_1 from the solution.

```
In [7]:
         `u = convex_mpc(A,B,X_ref_window,xic,xg,u_min,u_max,N_mpc)`
        setup and solve the above optimization problem, returning the
        first control u_1 from the solution (should be a length nu
        Vector{Float64}).
        function convex_mpc(A::Matrix, # discrete dynamics matrix A
                             B::Matrix, # discrete dynamics matrix B
                             X_ref_window::Vector{Vector{Float64}}, # reference trajectory for this window
                             xic::Vector, # current state x
                             xg::Vector, # goal state
                             u min::Vector, # lower bound on u
                            u_max::Vector, # upper bound on u
                             N mpc::Int64, # length of MPC window (horizon)
                             )::Vector{Float64} # return the first control command of the solved policy
            # get our sizes for state and control
            nx,nu = size(B)
            # check sizes
            @assert size(A) == (nx, nx)
            @assert length(xic) == nx
            @assert length(xg) == nx
            @assert length(X_ref_window) == N_mpc
            # LQR cost
            0 = diagm(ones(nx))
            R = diagm(ones(nu))
